1. Metawebs, i.e. networks of potential interactions within a species pool, are a powerful abstraction to understand how large-scales species interaction networks are structured.
2. Because metawebs are typically expressed at large spatial and taxonomic scales, assembling them is a tedious and costly process; predictive methods can help circumvent the limitations in data deficiencies, by providing 'draft' metawebs.
3. One way to improve the predictive ability is to maximize the information used for prediction, by using graph embeddings rather than the list of species interactions. Graph embedding is an emerging field in machine learning that holds great potential for ecological problems.
4. In this perspective, we outline how the challenges associated with inferring metawebs line-up with the advantages of graph embeddings; furthermore, because metawebs are inherently spatial objects, we discuss how the choice of the species pool has consequences on the reconstructed network, but also embeds hypotheses about which human-made boundaries are ecologically meaningful.

1 Being able to infer *potential* interactions could be the catalyst for significant breakthroughs in our ability
2 to start thinking about species interaction networks over large spatial scales (Hortal et al., 2015). In a
3 recent overview of the field of ecological network prediction, Strydom, Catchen, et al. (2021) identified
4 two challenges of interest to the prediction of interactions at large scales. First, there is a relative scarcity
5 of relevant data in most places globally – paradoxically, this restricts our ability to infer interactions to
6 locations where inference is perhaps the least required; second, accurate predictions often demand
7 accurate predictors, and the lack of methods that can leverage small amount of data is a serious
8 impediment to our global predictive ability. In most places, our most reliable biodiversity knowledge is
9 that of a species pool: through the analysis of databases like GBIF or IUCN, it is possible to establish a list
10 of species in a region of interest; but establishing the interactions between these species is difficult.

11 Following the definition of Dunne (2006), a metaweb is the ecological network analogue to the species
12 pool; specifically, it inventories *potential* interactions between species from a spatially delimited area (and
13 so captures the γ diversity of interactions). The metaweb is not a prediction of the network at a specific
14 point within the spatial area it covers: it will have a different structure, notably by having a larger
15 connectance (see *e.g.* Wood et al., 2015), from any of these local networks. These local networks
16 (capturing the α diversity of interactions) are a subset of the metaweb’s species and interactions, and have
17 been called “metaweb realizations” (Poisot et al., 2015). Differences between local networks and their
18 metawebs are due to chance, species abundance and co-occurrence, local environmental conditions, and
19 local distribution of functional traits, among others.

20 Because the metaweb represents the joint effect of functional, phylogenetic, and macroecological
21 processes (Morales-Castilla et al., 2015), it holds valuable ecological information. Specifically, it is the
22 “upper bounds” on what the composition of the local networks can be (see *e.g.* McLeod et al., 2021). These
23 local networks may be reconstructed given appropriate knowledge of local species composition, providing
24 information on structure of food webs at finer spatial scales. This has been done for example for
25 tree-galler-parasitoid systems (Gravel et al., 2018), fish trophic interactions (Albouy et al., 2019), tetrapod
26 trophic interactions (O’Connor et al., 2020), and crop-pest networks (Grünig et al., 2020). In this
27 contribution, we highlight the *probabilistic* nature of metawebs, discuss how a family of machine learning
28 tools (graph embeddings and transfer learning) can be used to overcome data limitations to metaweb
29 inference, and highlight how the use of metawebs introduces important questions for the field of network
30 ecology.

The metaweb is an inherently probabilistic object

Dallas et al. (2017) suggested that most links in ecological networks are cryptic, *i.e.* uncommon or hard to observe. This argument echoes Jordano (2016): sampling ecological interactions is difficult because it requires first the joint observation of two species, and then the observation of their interaction. In addition, it is generally expected that weak or rare links would be more common in networks (Csermely, 2004), compared to strong, persistent links; this is notably the case in food chains, wherein many weaker links are key to the stability of a system (Neutel et al., 2002). In the light of these observations, we expect to see an over-representation of low-probability interactions under a model that accurately predicts interaction probabilities. Yet the original metaweb definition, and indeed most past uses of metawebs, was based on the presence/absence of interactions. Moving towards *probabilistic* metawebs, by represent interactions as Bernoulli events (see *e.g.* Poisot et al., 2016), offers the opportunity to weigh these rare interactions appropriately. The inherent plasticity of interactions is important to capture: there have been documented instances of food webs undergoing rapid collapse/recovery cycles over short periods of time (*e.g.* Pedersen et al., 2017). These considerations emphasize why metaweb predictions should focus on quantitative (preferentially probabilistic) predictions; this should constrain the suite of appropriate models.

Yet it is important to recall that a metaweb is intended as a catalogue of all potential interactions, which is then filtered (Morales-Castilla et al., 2015). In a sense, that most ecological interactions are elusive can call for a slightly different approach to sampling: once the common interactions are documented, the effort required in documenting each rare interaction will increase exponentially, and will do so for each undocumented interaction. Recent proposals suggest that machine learning algorithms, in these situations, can act as data generators (Hoffmann et al., 2019): high quality observational data can generate the core rules underpinning the network structure, and be supplemented with synthetic data coming from predictive models, increasing the volume of information available for inference. Indeed, Strydom, Catchen, et al. (2021) suggested that knowing the metaweb may render the prediction of local networks easier, because it fixes an “upper bound” on which interactions can exist. A probabilistic metaweb represents an aggregation of informative priors on the interactions, an elusive information with the potential to boost our predictive ability (**Bartomeus2016ComFra?**).

[Figure 1 about here.]

59 Graph embedding offers promises for the inference of potential 60 interactions

61 Graph embedding fig. 1 is a varied family of machine learning techniques aiming to transform nodes and
62 edges into a vector space (Arsov & Mirceva, 2019), usually of a lower dimension, whilst maximally
63 retaining key properties of the graph (Yan et al., 2005). Ecological networks are an interesting candidate
64 for the widespread application of embeddings, as they tend to possess a shared structural backbone (Mora
65 et al., 2018), which hints at structural invariants that can be revealed at lower dimensions. Indeed,
66 previous work by Eklöf et al. (2013) suggests that food webs are inherently low-dimensional objects, and
67 can be adequately represented with less than ten dimensions. Simulation results by Botella et al. (2022)
68 suggest that there is no best method to identify architectural similarities between networks, and that
69 multiple approaches need to be tested and compared to the network descriptor of interest. This matches
70 with previous, more general results on graph embedding, which suggest that embedding algorithm choice
71 matters for the results (Goyal & Ferrara, 2018). In tbl. 1, we present a selection of common graph
72 embeddings methods, alongside examples of their use to predict species interactions (when they have
73 been used this way).

Table 1: Overview of some common graph embedding approaches, by time of publication, alongside examples of their use in the prediction of species interactions. Surprisingly, these methods have not yet been used routinely to predict species interactions; most of the examples we identified were either statistical associations, or analogues to joint species distribution models. ^a: statistical interactions; ^b: joint-SDM-like approach.

Method	Embedding approach	Reference	Application
tSNE	nodes through statistical divergence	Hinton & Roweis (2002)	Cieslak et al. (2020) ^a
RDPG	graph through SVD	Young & Scheinerman (2007)	Poisot et al. (2021)

GraphKKE	graph embedding	Melnyk et al. (2020)	Melnyk et al. (2020) ^a
Joint methods	multiple graphs	S. Wang et al. (2021)	

74 The popularity of graph embedding techniques in machine learning is more prosaic than the search for
 75 structural invariants: graphs are discrete objects, and machine learning techniques tend to handle
 76 continuous data better. Bringing a sparse graph into a continuous, dense vector space (Xu, 2020) opens up
 77 a broader variety of predictive algorithms, notably of the sort that are able to predict events as probabilities
 78 (Murphy, 2022). Furthermore, the projection of the graph itself is a representation that can be learned;
 79 Runghen et al. (2021), for example, used a neural network to learn the embedding of a network in which
 80 not all interactions were known, based on nodes metadata. This example has many parallels in ecology
 81 see 2, in which node metadata can be given by phylogeny or functional traits. Rather than directly
 82 predicting biological rules (see *e.g.* Pichler et al., 2020 for an overview), which may be confounded by the
 83 sparse nature of graph data, learning embeddings works in the low-dimensional space that maximizes
 84 information about the network structure. This approach is further justified by the observation, for
 85 example, that the macro-evolutionary history of a network is adequately represented by some graph
 86 embeddings (RDGP; see Dalla Riva & Stouffer, 2016).

[Figure 2 about here.]

The metaweb embeds strong ecological hypotheses

As Herbert (1965) rightfully pointed out, “[y]ou can’t draw neat lines around planet-wide problems”; in this regard, any inference of a metaweb at large scales must contend with several interesting and interwoven families of problems.

The first is the spatial and taxonomic limit of the metaweb to embed and transfer. If the initial metaweb is too narrow in scope, notably from a taxonomic point of view, the chances of finding another area with enough related species (through phylogenetic relatedness or similarity of functional traits) to make a reliable inference decreases; this would likely be indicated by large confidence intervals during estimation of the values in the low-rank space, but the lack of well documented metawebs is currently preventing the development of more concrete guidelines. The question of phylogenetic relatedness and dispersal is notably true if the metaweb is assembled in an area with mostly endemic species, and as with every predictive algorithm, there is room for the application of our best ecological judgement. Conversely, the metaweb should be reliably filled, which assumes that the S^2 interactions in a pool of S species have been examined, either through literature surveys or expert elicitation.

TK Supp. Mat. 1 provides some guidance as to the type of sampling effort that should be prioritized. While RDPG was able to maintain very high predictive power when interactions were missing, the addition of false positive interactions was immediately detected; this suggests that it may be appropriate to err on the side of “too many” interactions when constructing the initial metaweb to be transferred.

The second series of problems are related to determining which area should be used to infer the new metaweb in, as this determines the species pool that must be used.

TK In our application, we focused on the mammals of Canada. The upside of this approach is that information at the country level is likely to be required by policy makers and stakeholders for their biodiversity assessment, as each country tends to set goals at the national level (Buxton et al., 2021) for which quantitative instruments are designed (Turak et al., 2017), with specific strategies often enacted at smaller scales (Ray et al., 2021). And yet, we do not really have a satisfying answer to the question of “where does a food web stop?”; the current most satisfying solutions involve examining the spatial consistency of network area relationships (Fortin et al., 2021; see e.g. Galiana et al., 2018, 2019, 2021), which is of course impossible in the absence of enough information about the network itself. This suggests that an *a posteriori* refinement of the results may be required, based on a downscaling of the metaweb.

117 The final family of problems relates less to the availability of data or quantitative tools, and more to the
118 praxis of spatial ecology. Operating under the context of national divisions, in large parts of the world,
119 reflects nothing more than the legacy of settler colonialism. Indeed, the use of ecological data is not an
120 apolitical act (Nost & Goldstein, 2021), as data infrastructures tend to be designed to answer questions
121 within national boundaries, and their use both draws upon and reinforces territorial statecraft; as per
122 Machen & Nost (2021), this is particularly true when the output of “algorithmic thinking” (e.g. relying on
123 machine learning to generate knowledge) can be re-used for governance (e.g. enacting conservation
124 decisions at the national scale). We therefore recognize that methods such as we propose operate under
125 the framework that contributed to the ongoing biodiversity crisis (Adam, 2014), reinforced environmental
126 injustice (Choudry, 2013; Domínguez & Luoma, 2020), and on Turtle Island especially, should be replaced
127 by Indigenous principles of land management (Eichhorn et al., 2019; No’kmaq et al., 2021). As we see
128 AI/ML being increasingly mobilized to generate knowledge that is lacking for conservation decisions (e.g.
129 Lamba et al., 2019; Mosebo Fernandes et al., 2020), our discussion of these tools need to go beyond the
130 technical, and into the governance consequences they can have.

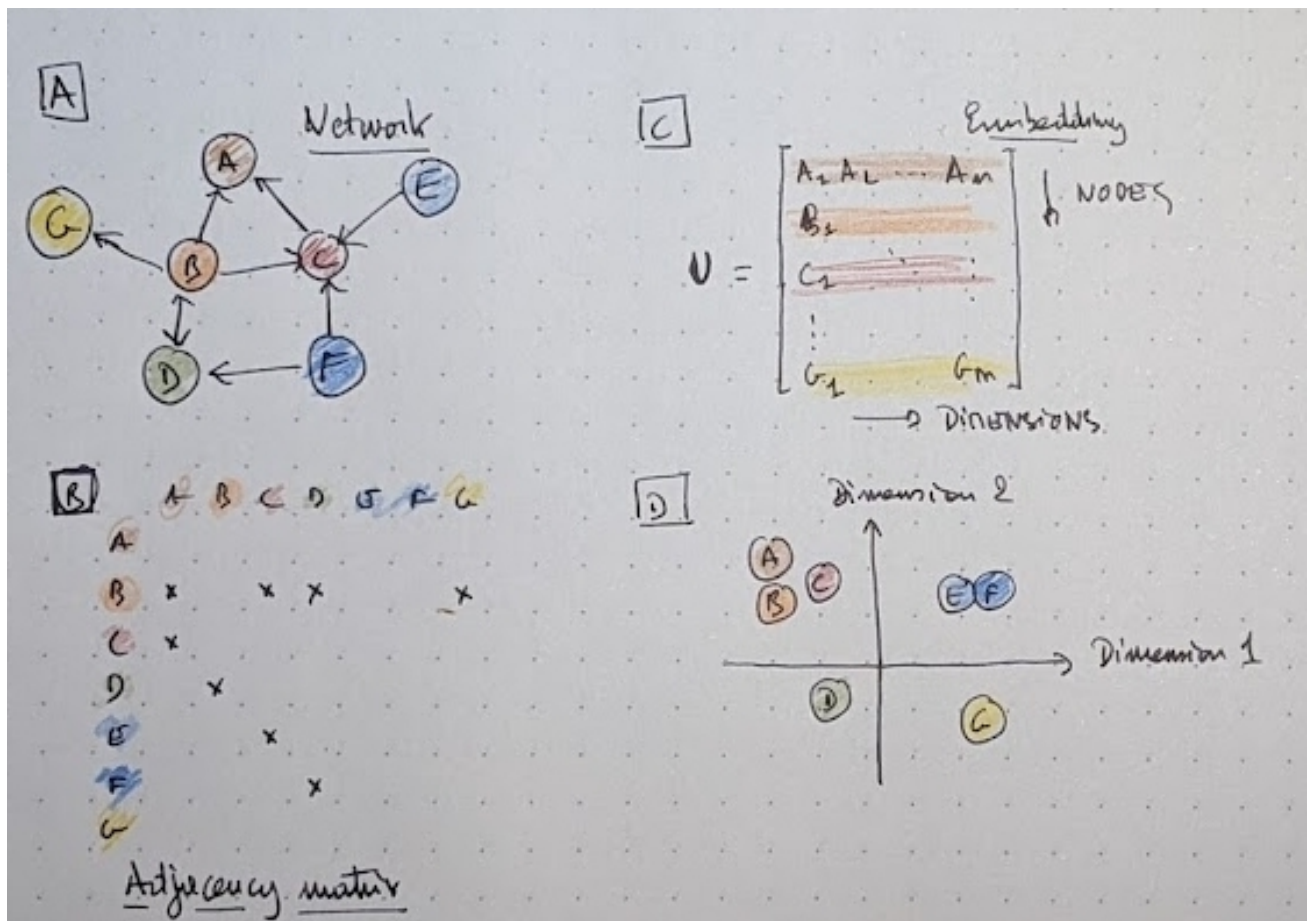

Figure 1: Overview of the embedding process. A network (A), possibly represented as its adjacency matrix (B), is converted into a lower-dimensional object (C) where nodes, subgraphs, or edges have specific values (see tbl. 1). For the purposes of prediction, this low-dimensional object encodes feature vectors for e.g. the nodes. Embedding also allows to visualize the structure in the data differently (D), much like with a principal component analysis.

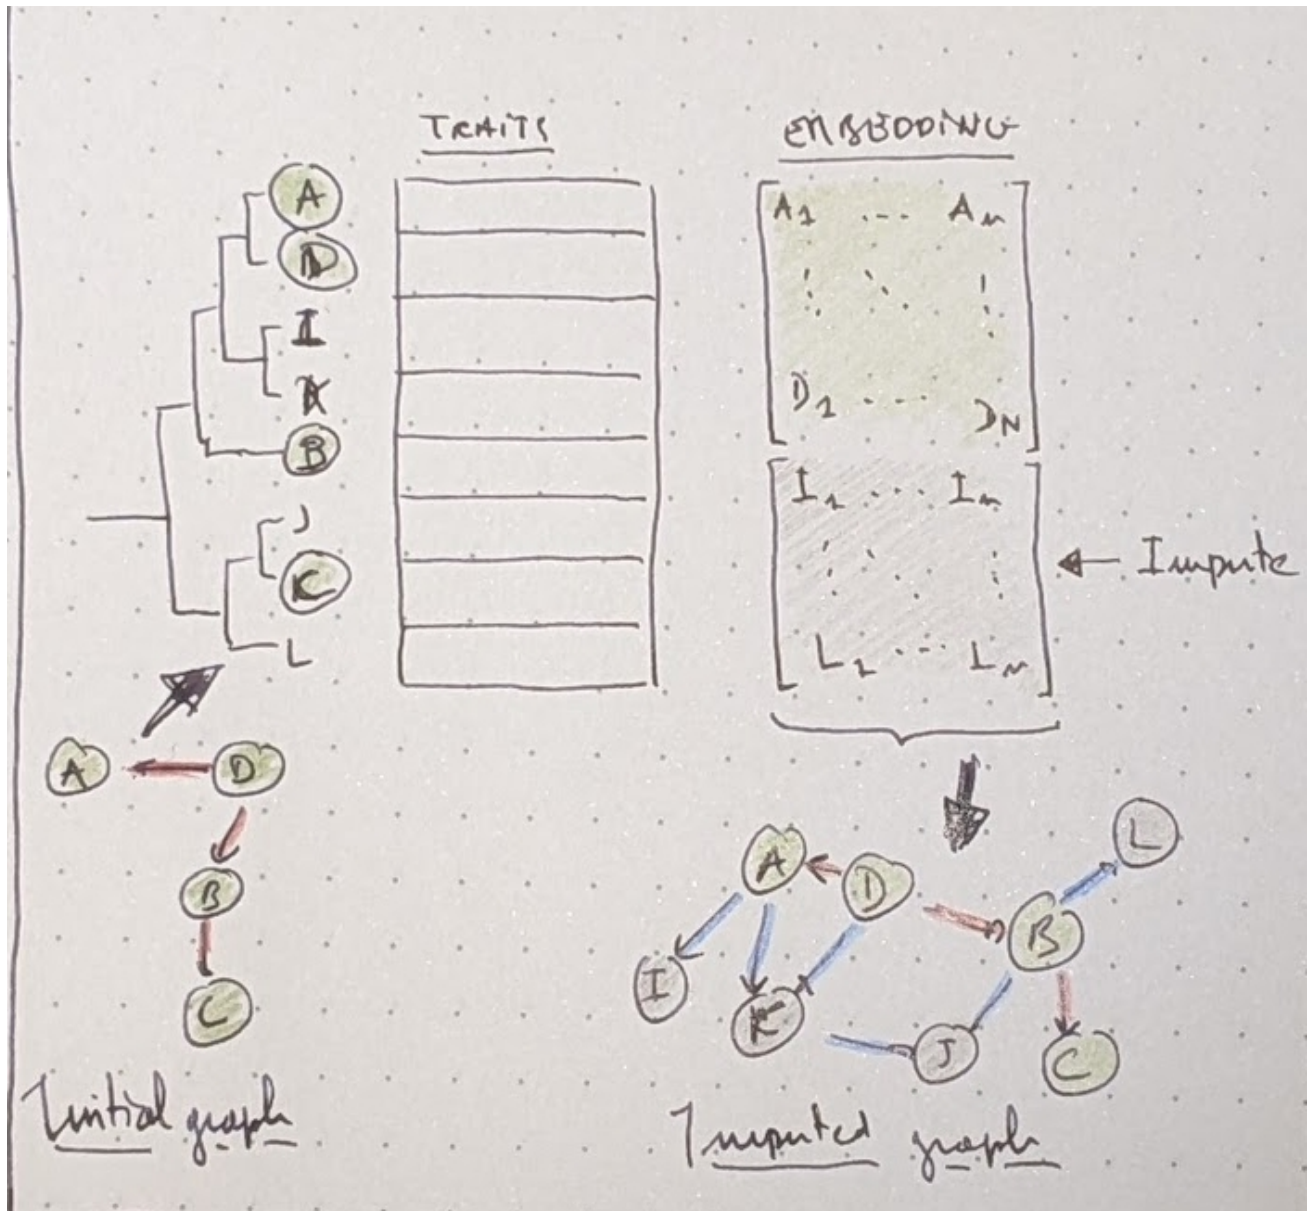

Figure 2: From a low-dimensional feature vector (see fig. 1), it is possible to develop predictive approaches. Nodes in an ecological network are species, for which we can leverage phylogenetic relatedness (e.g. Strydom, Bouskila, et al., 2021) or functional traits to fill the values of additional species we would like to project in this space (here, I, J, K, and L) from the embedding of known species (here, A, B, C, and D). Because embeddings can be projected back to a graph, this allows to reconstruct a network with these new species. This approach constitutes an instance of transfer learning.
